Objective

To explore geographic variation in diabetes prevalence at the state level for 4 domains from the National Health Interview Survey (NHIS).
Outline

1. Data
2. Design based estimates
3. Within states covariances
4. Covariates
5. Models
6. Model Fit
7. Results
8. Simulations
9. Conclusions
Pooling and Weighting

1. Due to the small sample sizes at the state level, the corresponding sample variance is too unstable.

2. The data are pooled for the years 2006 – 2015. *Note that even if data are pooled, the number of PSUs per state remain constant. A traditional variance of the $S^2$ form may still be unstable.*

3. The data are weighted to adjust to population totals. Interim sampling weights are used in this analysis.

4. The value of the interim sampling weight is roughly the number of people a given sample adult or sample child represents.

5. Due to the changes in NHIS sample size between 2006 and 2015 the Interim sampling weights need to be adjusted for the pooling across all 10 years.

NHIS design based estimates using a SAS survey procedure

1. proc surveylogistic
2. stratum STRATA
3. cluster PSU
4. by STATE
5. class DOMAIN
6. model DIABETIC(event=’1’) = DOMAIN/noint covb
7. weight $w_{ik}$
8. $w_{ik}$ is the final survey weight adjusted by proportions for ith year and kth individual from 2006-2015
Estimates from SAS/SURVEYLOGISTIC

1. 204 diabetes rates: 51 states/DC x 4 domains
2. 4x4 variance/covariance matrices for 4 domains within 51 states
3. US level variance/covariance matrix $\hat{\Omega}$

4. US national level design effects for four domains
5. DF (degrees of freedom) for each of 51 states/DC
Adjustment on variance/covariance matrices for small states

1. Let $D_i = (\hat{\Sigma}_i[1, 1], \hat{\Sigma}_i[2, 2], \hat{\Sigma}_i[3, 3], \hat{\Sigma}_i[4, 4])$ as a $4 \times 1$ is a vector of the diagonal elements of $\hat{\Sigma}_i$ for state $i$, where $i = 1, \ldots, 51$

2. Let $U = (\hat{\Omega}[1, 1], \hat{\Omega}[2, 2], \hat{\Omega}[3, 3], \hat{\Omega}[4, 4])$ as a $4 \times 1$ is a vector of the diagonal elements of $\hat{\Omega}$

3. Let $T$ be a $4 \times 4$ diagonal matrix whose elements are $\sqrt{D_i/U}$. Thus the covariance matrix can be estimated as: $\hat{\Sigma}_i^* = T \cdot \hat{\Omega} \cdot T$, where, we pre- and post-multiply $T$ with $\hat{\Omega}$ to obtain $\hat{\Sigma}_i^*$

4. $\hat{\Sigma}_i^*$ maintains the variance estimates for the corresponding state and four domains

5. $\hat{\Sigma}_i^*$ uses the correlation estimates from the national level covariance estimates matrix for the diabetes prevalence

6. The adjusted covariance matrix estimates $\hat{\Sigma}_i^*$ were used in the model estimation
1. Diabetes data from years 2006-2015 were downloaded from BRFSS website
2. Data were pulled and sample weights were adjusted across 10 years
3. 204 diabetes rates (51 states x 4 domains) were computed using SAS/SurveyFreq by incorporating BRFSS sampling design variables (stratum and PSU)
1. Hierarchical Bayes models

3. Additional covariates such as obesity, poverty, income and others were obtained from United States Department of Agriculture (USDA) and Area Resource File (ARF) datasets

4. Hierarchical Bayes estimates borrow strength over space (states) to produce SAEs
1. $\hat{Y}_i$: diabetes prevalence estimate in state $i$ on a logit scale where, $\hat{Y}_i = (\hat{y}_i^1, \hat{y}_i^2, \hat{y}_i^3, \hat{y}_i^4)$, for $i = 1, \ldots, 51$ states and 4 domains.

2. The multivariate FH model can be defined as: $\hat{Y}_i \sim MVN(\mu_i, \hat{\Sigma}_i)$, where, $\mu_i = (\mu_i^1, \mu_i^2, \mu_i^3, \mu_i^4)$ denotes unknown diabetic prevalence that is to be estimated for state $i$ and 4 domains $\hat{\Sigma}_i$ is the estimated design-based estimate of variance-covariance matrix of $\mu_i$ for state $i$ and 4 domains on a logit scale.
Proposed models

Model 1: Intercepts with random effects

\[ \mu_{ij} = \alpha_{0j} + v_{ij} \]

1. \( \alpha_{0j} \): an intercept for each domain which is assigned a vague distribution: flat prior, \( \alpha_{0j} \sim dflat() \)

2. \( v_{ij} \): random effects by state \( i (i=1,...,51) \) and domain \( j (j=1,2,3,4) \). Specifically, if \( v_i = (v_{i1}, v_{i2}, v_{i3}, v_{i4}) \), then \( v_i \sim MVN(0, R) \)

Inverse of \( R \) is assigned a Wishart prior with \( I \) as the scale matrix and degrees of freedom = 4

\[
R^{-1} \sim \text{Wish} \left( \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}, 4 \right)
\]
Proposed models

Model 2: Model 1 + BRFSS covariates

1. $\mu_{ij} = \alpha_{0j} + v_{ij} + X_{ij}'\beta_j$

2. $\alpha_{0j}$: Intercept for each domain assigned vague distribution: flat prior
   $X_{ij}$: is the $i$th row of the covariates matrix

3. $v_{ij}$: random effects by state $i$ ($i=1,...,51$) and domain $j$ ($j=1,2,3,4$). Specifically, if $v_i = (v_{i1}, v_{i2}, v_{i3}, v_{i4})$, then $v_i \sim MVN(0, R)$

4. Inverse of $R$ is assigned a Wishart prior with $I$ as the scale matrix and degrees of freedom $= 4$
   $\begin{pmatrix}
   1 & 0 & 0 & 0 \\
   0 & 1 & 0 & 0 \\
   0 & 0 & 1 & 0 \\
   0 & 0 & 0 & 1
   \end{pmatrix}$

5. Inverse of $R \sim Wish \left( \begin{pmatrix}
   1 & 0 & 0 & 0 \\
   0 & 1 & 0 & 0 \\
   0 & 0 & 1 & 0 \\
   0 & 0 & 0 & 1
   \end{pmatrix}, 4 \right)$

6. $\beta_j$: vector of regression parameters. Normally distributed with uniform priors $U(0,100)$ on the standard deviation
Proposed models

Model 3: Model 1 + ARF and USDA covariates

1. \( \mu_{ij} = \alpha_{0j} + v_{ij} + Z_i' \gamma \)

2. \( \alpha_{0j} \): Intercept for each domain assigned vague distribution: flat prior

3. \( v_{ij} \): random effects by state \( i \) (\( i=1,...,51 \)) and domain \( j \) (\( j=1,2,3,4 \)). Specifically, if \( v_i = (v_{i1}, v_{i2}, v_{i3}, v_{i4}) \), then \( v_i \sim \text{MVN}(0, R) \)
   Inverse of \( R \) is assigned a Wishart prior with \( I \) as the scale matrix and degrees of freedom = 4
   \[
   \begin{pmatrix}
   1 & 0 & 0 & 0 \\
   0 & 1 & 0 & 0 \\
   0 & 0 & 1 & 0 \\
   0 & 0 & 0 & 1 \\
   \end{pmatrix}, 4
   \]
   Inverse of \( R \sim \text{Wish} (I, 4) \)

4. \( Z_i \): is the \( i \) th row of the covariates matrix

5. \( \gamma \): vector of regression parameters
   \( \gamma \): assigned vague distribution: flat prior
Proposed models

Model 4

1. In model 4, the effect of ignoring the correlations between the different domains was investigated.

2. The off diagonal elements of the matrices $\hat{\Sigma}_i$, the design-based estimate of variance-covariance matrix of $\hat{\mu}_i$ for state $i$ and 4 domains were set to zero. Specifically, $\hat{\Sigma}_i = \text{diag}(\hat{\Sigma}_i)$. Hence, model 4 is defined as:

$$\mu_{ij} = \alpha_{0j} + v_{ij} + X_{ij}' \beta,$$

where, $\alpha_{0j}$, $v_{ij}$, and $X_{ij}' \beta$, are defined above as in model 2.
Proposed models

Model 5

1. In model 5, the advantage of using ARF and USDA covariates and BRFSS diabetes prevalence estimates together in one model is further investigated.

2. Model 5 is defined as:
   \[ \mu_{ij} = \alpha_{0j} + \nu_{ij} + X_{ij}'\beta_j + Z_i'\gamma, \]
   where, \( \alpha_{0j}, \nu_{ij}, X_{ij}'\beta_j, \) and \( Z_i'\gamma \) are defined above as in model 2 and model 3.

Figure 16: Standard errors for survey design based estimates and posterior standard deviations for model based SAEs for domain 4: Females above 64.
1. Used the direct design based diabetes prevalence NHIS estimates and the corresponding design based covariance matrix estimates as truth to generate artificial populations for 1000 cases

2. Specifically, in the simulation, for state $i$, where $i = (1, \ldots, 51)$, it is assumed that the population values are: $\mu_i^* = \hat{Y}_i$

3. Assume the sample covariance for state $i$ is: $\Sigma_i^* = \hat{\Sigma}_i$

4. If $\hat{\Sigma}_i$ is non-singular then simulate samples from the population according to the sample design. Specifically, for state $i$ where, $\hat{\Sigma}_i$ is non-singular,

$$Y_i^{(f)} \sim MVN(\mu_i^*, \hat{\Sigma}_i^*)$$

and

$$Df_i \times \hat{\Sigma}_i^f \sim Wish(Df_i, \hat{\Sigma}_i^*),$$

where $Df_i =$ degrees of freedom (number of PSUs - number of strata) for state $i$
Simulation study - Evaluation through simulation

1. For state $i$, where, $\hat{\Sigma}_i$ is singular, use the matrices $\hat{\Sigma}_i^{**}$ proposed in slide 9

2. Fitted the Bayesian model to 1000 simulated datasets to determine simulated diabetes prevalence estimates $\mu_i^*$ for $i = 1, \ldots, 51$ states

3. Evaluated the accuracy of estimates via the coefficient of variations (CVs) (Root Mean Squared Error (RMSE)/ design based estimate)

4. RMSE is defined as:
   
   $RMSE = \sqrt{\frac{1}{G} \sum_{g=1}^{G}(\mu_i - \hat{\mu}_i)}$, where $G$ denotes the total number of simulated cases
Figure 17: RMSE/NHIS design-based value vs design based variance (in decreasing order) for 150000 vs 300000 samples
Simulation study - 150000 vs 300000 samples

Figure 18: RMSE/NHIS design-based value vs design based variance (in decreasing order) for 150000 vs 300000 samples
Figure 19: RMSE/NHIS design-based value vs design based variance (in decreasing order)
Simulation study - Domain 2

Figure 20: RMSE/NHIS design-based value vs design based variance (in decreasing order)
Figure 21: RMSE/NHIS design-based value vs design based variance (in decreasing order)
Figure 22: RMSE/NHIS design-based value vs design based variance (in decreasing order)
Conclusions

1. There might be some error in the covariate estimates
2. All ARF variables were non-significant
3. BRFSS estimates as covariates: one domain was highly correlated with design based NHIS estimates
4. High Diabetes prevalence was found to be in: Oklahoma, West Virginia, Ohio, Kentucky, Indiana, South Carolina, Missouri, Mississippi, Tennessee, Virginia, North Carolina, Texas, Alabama and some pockets in the western U.S.
5. This method can provide improved estimates (coefficient of variation is less than or equal to 0.3)
6. The simulation study checks for model failures that are important to inference

2. Thanks.
